# Re-calibration of SOAR speckle data 

## Authors:A. Tokovinin

Version: 2
Date: Feb 1, 2016
File: prj/speckle/doc/SAM16/recalibration/recal.tex

## 1 Introduction

Accurate calibration of speckle interferometry is not an easy task. The field of view is normally small, so the established astrometric standards like globular clusters or Orion Trapezium are not useful. Orbits of binary stars are normally less accurate than the data, so their use for calibration does more harm than good. Only orbits based on long-baseline interferometry, with accuracy exceeding speckle, can be used as calibrators, but those binaries are mostly quite close. On the other hand, wide binaries with separation above 1 arcsec should be used as calibrators because they allow measurement of scale and angle offset with higher accuracy, compared to the close pairs.

Absolute (i.e. independent of standards) calibration of speckle instruments has been done in the past. A two-slit mask placed in front of the telescope and an interference filter with well-known transmission allow such calibration, provided that the mask orientation is tied to the parallactic angle and that the mask is in the pupil and not in other place, where an additional scale factor must be accurately determined. At SOAR, absolute calibration has been done in 2009 using laser interference fringes and atmospheric dispersion to ascertain the angle. More recently, the SOAR HRCam has been tied astrometrically to the SOAR CCD imager (SAMI) with a $3^{\prime}$ field. This relation is established by moving the point source in the focal plane and measuring its pixel coordinates in both instruments. Distortion in SAMI images is removed and they are calibrated astrometrically against 2MASS or other catalogs, providing orientation and pixel scale for SAMI and, hence, for HRCam.

Most runs of HRCAM were not accompanied by absolute calibration, however. Some (e.g. in 2012) used only the internal point-source calibration, relying on correct orientation and stable focus provided by the telescope. Short runs of only a few hours were not calibrated independently and "borrowed" calibration parameters from previous or posterior runs.

Fortunately, in every run several wide binaries were always observed with the idea to use them for calibration post factum when their motion is accurately determined by other means. Such "anchor" binaries can be also used to test the internal consistency of the full HRCam data set. Systematic errors were evident (Fig. 1).

The first step in this direction was taken in 2014, see the SOAR2014 paper. A set of 41 binaries wider than $0.5^{\prime \prime}$ without known subsystems, each observed in at least 4 runs, was selected. The motion in $\theta$ and $\rho$ was approximated by linear functions of time. Then for each run deviations of the observed subset of calibrators from their linear ephemeris were median-averaged to determine systematic corrections for this run. After applying these corrections, the linear models were updated, new run corrections were found, etc. After several iterations the process converged. The resulting typical rms differences between models and calibrated data were $0.1^{\circ}$ in angle and 1.9 mas in separation.

Figure 1: Speckle data before recalibration. Left: JC 8 AB (03124-4425), right: HJ 1399 (06003-3102). Scale in arcseconds, North up, East left, primary at ( 0,0 ). In each plot, squares connected by full line are the measurements, dashed line is the current orbit, dotted lines connect measurements to predicted positions.

Here this procedure is repeated with a few modifications, resulting in more robust estimation of the calibration parameters. I now included calibrators observed in only 3 runs and modeled the motion of orbital binaries more accurately. The set of calibrators is thus extended. They are by no means an ideal set, but rather the random set that happens to have adequate observations with HRCam.

It should be noted that a systematic error in scale or orientation common to all runs would remain undetected by this self-calibration procedure.

## 2 Modified calibration procedure

The new procedure is implemented in the code recalib3.pro which contains several programs. It should be launched from the main directory, where all necessary binary files such as allruns.idl are found. Recalibration is described step by step in the following.

1. The preliminary list of calibrators recalib3.txt is formed by getstars. Criteria: minimum average separation $0.5^{\prime \prime}$, data in no less than 3 runs. The list also contains HIP numbers and flags if orbits are known.
2. In the edited version recalib3a.txt many entries are eliminated (commented out) because they contain resolved subsystems. This is done by examination of all data on each system. Note that for some calibrators the sub-systems listed in the WDS (e.g. FIN $317 \mathrm{Aa}, \mathrm{Ab}$ in 09125-4337) are not confirmed at SOAR, and those are retained as simple binaries. A few pairs are removed because of their large $\Delta m$, hence large measurement errors. Nevertheless, the new list counted 73 calibrators with a total of 418 observations, or 5.7 runs per calibrator on average.
3. The structure recalib is created by getrecalib by reading the edited file. Its elements are:
```
el0 = {wds:'',,name:'',,hip:0L,rho:0.0,dm:0.0,nruns:0,type:1,el:dblarr(10),rmstheta:0.,rmsrho:0.
```

The type defines the nature of the data. Type 1 is the linear motion, in which case the first 5 elements of the array are $\left(t_{0}, \theta_{0}, \dot{\theta}, \rho_{0}, \dot{\rho}\right)$. Type 2 are orbital pairs, where the first 7 numbers are orbital elements ( $P, T, e, a, \Omega, \omega, i)$.
4. Collect measurements of all calibrators using getobs. It creates the structure dat, saved in recaldat.idl, with elements:
el0 = \{name:'',irun:-1,t:0.0,theta:0.0,rho:0.0\}
Several measurements in one run are averaged, without regards of filters. The $\Delta m$ parameter is also average over all filters.
5. Add measurements from Hipparcos using gethipdat. Some pairs with HIP numbers do not have such measurements, being unresolved by Hipparcos.
6. Fit linear elements to binaries of type 1 with fitlin procedure. It takes the name of the star as input and returns the parameters and the rms residuals. Its keywords are /iterate (correct for run systematics before fitting), /nohip (do not use HIP point in the fitting), /save (put the results and rms residuals into recalib, /runname (read run corrections from another file, rather that default). In the first pass of fitting, the run corrections determined in 2014 were used. The procedure alllin fits all linear elements. In most cases I ignored the HIP point, as it is spaced too far in time from the HRCam data set and increases the residuals because of the non-linear orbital motion. The HIP datum is used only for some calibrators with just 3 HRCam points and slow motion.
7. Collect orbital elements from VB6 using getorbit. It selects data from VB6 matching both WDS and object name. If no or several matches are found, the selection is done manually for this object.
8. Updating the orbits. The procedure allinp creates for each type-2 binary the file NAME.inp in the sub-directory orb that lists orbital elements and data (only HIP and HRCAM, extracted from dat) in a format suitable for the orbit program. The HRCAM data are corrected for the run systematics, but uncorrected for precession in angle. By default, all elements except ( $T, a, \Omega$ ) are fixed. Using orbit, I adjusted the 3 free elements to match the data. HRCAM data have a weight 25 times larger than HIP, according to the square ratio of respective measurement errors. In some cases, I also fitted $\omega$ and/or $i$ to reach reasonably small residuals of a few mas. When even this failed, a more thorough revision of some orbits was attempted [Give list]. It should be stressed that the adjusted orbits serve only as good approximations of the HRCAM data, regardless of their quality in other aspects. Figure 2 gives two examples.

The HIP measure of STF 186 was flipped. The orbits of 22451-0240 (A 2696 BC) and 23171-1349 (BU 182 AB ) could not be adjusted to give reasonably small residuals, so linear fits were done instead. Overall, there are 50 calibrators of type 2 (orbital) and 23 of type 1 (linear). However, 01361-2954 (HJ 3447) is removed from calibrators owing to large residuals. Apparently it contains a subsystem.
9. Ingest the updated orbits into recalib using allorbit. It simply reads the new elements from the NAME.out files and replaces them. The orbit adjustment can then be repeated by creating a new set of *.inp files that use better corrections for the runs.
10. Examine all data using plotstar. It plots the run-corrected observations and their models, either linear or orbital. The procedure ephstar computes the latter, given type and elements. The keyword /save allows to update the residuals in recalib. The allplot plots all stars in the list sequentially, with a stop to examine the plot.

Figure 2: Adjusted orbits. Left: JC $8 \mathrm{AB}, P=45.2 \mathrm{yr}$, rms 0.8/1.3 mas. Right: HDS $2412 \mathrm{Aa}, \mathrm{Ab}$, $P=41.3 \mathrm{yr}$, rms $0.7 / 0.6 \mathrm{mas}$.

Figure 3: Comparison between data and models for two orbital binaries. Left: JC $8 \mathrm{AB}, 0.8 / 1.3 \mathrm{mas}$ tangential/radial residuals, right: HU $1399 \mathrm{AB}, 2.3 / 1.2$ mas residuals.

Figure 3 gives examples of the plots for orbital binaries. Figure 4 shows HJ 3447 with large residuals (possibly undetected subsystem) and a linear model for B 1491. Overall, the rms residuals in tangential and radial directions are similar, with median values of 1.85 and 1.35 mas, respectively.
11. Iterate. The procedure fitruns re-computes the run corrections using observations and the models currently stored in recalib. The results are saved in the binary file runs3.idl. It contains the

Figure 4: Comparison between data and models. Left: HJ 3447 with large residuals of $9.1 / 6.3$ mas apparently caused by wobble, right: B 1491 with a good linear model, 1.6/1.3 mas.
array runs [nruns,3] where for each run the $\Delta \theta$, scale factor, and number of calibrators are stored, and the file eruns [nruns, 2] with rms residuals in $\theta$ (degrees) and $\rho$ (arcsec). The array yrmin is also saved with the beginning dates of each run, to facilitate the recalibration. The $\Delta \theta$ and scale have the sense of (O-C), so to correct for the run systematics they need to be applied in reverse (subtract and divide).

After the first determination of the elements, I iterated for the second time. The residuals decreased somewhat. No further iterations were made.
12. Listing of results and additional services.
liststars produces list of all calibrators liststars3.txt.
listruns creates listruns3.txt with calibrations of the runs.
listpar produces linpar.txt with linear elements and orbpar.txt with orbital elements.
biascor is a procedure to apply run corrections to a set of observations. The run data are read at the first call and kept in the common block for subsequent calls. The procedure corrrun uses this utility to remove systematics from any observing run. The corrected data are saved in a file with .corr added to the name, e.g. obsres.idl.corr.
checkrun finds calibrators in the given run and determines run corrections. It is useful for calibration of future runs.

## 3 Results

Figure 5 plots the systematic offsets found here. The scale is mostly within $0.2 \%$ from one, with the largest correction of $-0.5 \%$ for the run 26 (2014.85, replacement detector and different lens in the camera). The largest offsets in angle are $+0.6^{\circ}$ for the run 20 (2013.47, poor calibration) and $-0.4^{\circ}$ for run 15 (2012.83). The runs 10 and 19 remain without calibrators; however, they contain only a small number of measurements. The median values of the run corrections in absolute value are $0.13^{\circ}$ in angle and $0.1 \%$ for the scale. They are very similar to the medians of the rms scatters within each

Figure 5: Calibration parameters found here. The vertical lines show rms scatter for each run (not the error of the mean). Two runs without calibrators are marked by crosses.
run, $0.105^{\circ}$ and $0.18 \%$, respectively. This tells us that no further improvement in calibration accuracy is expected from continued iterations.

The rms residuals of calibrators in the radial and tangential directions are similar, with median values of 1.35 and 1.85 mas, respectively. For a typical $1^{\prime \prime}$ binary, the 2 -mas tangential error corresponds to $0.11^{\circ}$. However, some stars have larger residuals. HJ 3447 suggests a wobble caused by unrecognized subsystem, so it was removed from the calibrator set (Fig. 4). In some other cases one slightly deviant measure causes the large rms residuals.

As an example, I applied the recalibration corrections to all data of 2015 (runs 28 to 35). These runs were already checked vs. linear calibrators defined in 2014. Still, non-negligible corrections of $+0.20^{\circ}$ and $-0.32^{\circ}$ are found for the runs 28 and 30 (2015.10 and 2015.25), while the corrections in scale are all under $0.2 \%$. Before correction, the calibrators had rms residuals of $0.11^{\circ}$ and $0.26 \%$ for the 2015 data. After correction, the residuals decreased to $0.067^{\circ}$ and $0.23 \%$.

Corrections of systematics have only a tiny effect on the close binaries. For wide pairs, however, they help to determine more accurate orbital elements and to study deviations caused by subsystems. Such deviations with a period on the order of 10 yrs were found here for 01361-2954 (HJ 3447), known also as $\tau$ Scl, HR 462 ( $V=5.69$, sp. type F2, parallax 14.42 mas ). Its orbit with $P=1500 \mathrm{yr}$ is based only on a short observed arc, so it is not reliable. The system might belong to the Hyades supercluster according to O. Eggen.

## 4 Lists

The list of calibrators and resulting rms residuals (in mas), calibrators3.txt. Remarks in the last columns indicate dates single deviant measures or other reasons of rms residuals exceeding 4 mas.
